A seismic shift in thinking

Earthquake researchers in the United States have long shunned the word 'prediction'. But, thanks to improved data and a change in public perception, cracks are beginning to appear in their resolve. David Cyranoski tracks the debate.

Both phenomena illustrate the complexity of earthquake generation, a welcome advance for researchers who knew that the simple models used for predictions were 'fully incomplete'. If the complex system could be understood, prediction might be possible, says Kawasaki, who tracked a silent quake² in 1992. "These provide new perspectives that most people couldn't have imagined ten years ago," he says.

"Making predictions to the public must only be done with the consensus of the scientific community."

— Ichiro Kawasaki

Silent quakes and non-volcanic tremors have even been found together in the Cascadia subduction zone, off the coast of the northwest United States and Canada⁴. Retrospective data analyses show that these have occurred in large earthquakes. His most recent predic-

think it would work this well," he says. Rundle is also working on a map for Japan. On 23 October, a magnitude 6.8 quake hit Niigata — killing at least 25 people and injuring more than 2,000 — near one of Rundle's hotspots. Rundle says his maps reduce the total area known to be seismically active to 24% of active fault areas, which would help to allocate resources for retrofitting bridges and other vulnerable infrastructure. "I wish people would use it now," he says.

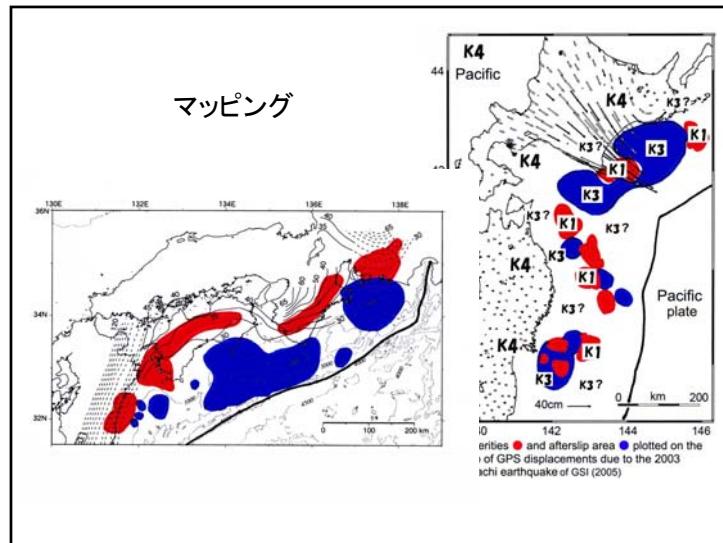

Kellis-Borok also uses statistics and patterns to make predictions: his algorithms are derived from histories of
